

Portfolio Construction: Turning Trade Ideas into a Rates Portfolio

An illustrative case study framed on a Q4 2025 portfolio setup, focused on risk interaction, horizon diversification, and macro portfolio design

Published: 2026-04-28 | Tags: Portfolio Construction • Fixed Income • Risk

An illustrative case study on turning individually attractive rates trades into a coherent portfolio risk structure.

This article is an illustrative case study in portfolio construction. It is based on public market information and simplified portfolio analytics. It is not investment advice, not a recommendation, and not a description of any live portfolio or employer-related activity.

Good Trades Are Only the Raw Material

A trade idea can be attractive on its own.

It may have valuation support, a catalyst, a favourable technical backdrop, and a clear asymmetry. But that does not make it a portfolio position.

A portfolio position has to do more than make sense in isolation. It has to earn its place inside a broader structure.

The starting point is usually a small set of trades that each represent value in their own right. Conviction builds when several drivers align: valuation, macroeconomics, supply, positioning, event risk, political context, liquidity, and relative value.

None of those factors is enough on its own.

The discipline is in the alignment.

But identifying good trades is only half the job. The other half - the part that determines whether a portfolio can survive a full cycle - is understanding how those trades interact.

A portfolio is not a scrapbook of good ideas. It is an interacting system.

Add one trade and the behaviour of every other trade changes. Add leverage and the emotional temperature of the portfolio changes. Add a hedge and one risk may fall while another risk is created somewhere else.

The trade idea is the raw material.

The portfolio is the product.

The Portfolio Is the Product

Start with the headline.

In the simplified illustrative analytics used for this case study, the selected trade expressions have 548bps of summed standalone quarterly volatility.

Taken individually, these are economically meaningful exposures with material mark-to-market

volatility.

But the portfolio does not behave like the sum of its parts.

Once the trades are combined, the aggregate marginal risk contribution is 255bps per quarter. In other words, diversification across strategies has more than halved the measured risk versus the summation of standalone volatility.

That gap is the story.

It is the difference between taking risk and constructing risk.

Measure	Quarterly Risk
Sum of standalone trade volatility	548bps
Aggregate marginal risk contribution	255bps
Risk compression factor	~2.15x
Share from two highest-conviction themes	~82%

Figure 1. Risk compression factor: portfolio risk is less than half the summed standalone volatility of its components.

The risk is not reduced by pretending it is smaller. It is reduced by understanding which exposures offset, which exposures reinforce, and which exposures are worth owning together.

Diversification is only useful when it is measurable.

The objective is not to eliminate risk. The objective is to make sure every unit of risk is doing useful work.

See Appendix A-E for the trade-expression notes behind the portfolio components.

Every Trade Needs a Job

A portfolio is not improved by adding more trades. It is improved by adding trades that change the shape of the outcome distribution.

Each position should have a job. If it does not, it does not belong in the portfolio.

In this illustrative case study, the portfolio can be understood through five broad roles:

Portfolio Role	What It Does	Typical Failure Mode
Tactical alpha	Captures stretched risk premium around a nearer-term catalyst	Catalyst fails or timing is wrong
Structural value	Owns slower-moving convergence or regime-change risk	Becomes dead money before convergence arrives
Shock absorber	Helps if fiscal, supply, or curve pressure rises	Stops offsetting when correlations shift
Political convexity	Benefits when political risk reprices	

Carry is not enough to
compensate for path risk

Credit defence

Provides protection if complacent
spread risk unwinds

Stress does not arrive, or liquidity
dominates

The important point is not that
every trade has the same
expected return. It does not.

Some positions are return
engines. Some are hedges.
Some are liquidity reserves.
Some are convexity providers.
Some are slow-burn structural
value trades.

Their value depends on the role
they play in the whole structure.

A trade that looks modest alone
may be extremely valuable if it
improves the shape of the
portfolio. Conversely, a brilliant
standalone trade may be
dangerous if it stacks the same
exposure the portfolio already
has.

That is why marginal
contribution to risk matters
more than emotional conviction.

See Appendix A-E for the trade-
specific rationale behind each
role.

The Hidden Risk Is Concentration

Two good trades can still
become one bad portfolio.

This is where portfolios often
fool themselves. The line items
look different. One trade may be
UK curve and asset swap risk.

Another may be long-dated EU relative value. Different jurisdictions, different tickers, different stories, different catalysts.

But under stress, they may both answer to the same underlying question:

Does the market want to own long-duration risk?

If the answer is yes, the portfolio may look well constructed.

If the answer is no, it may suddenly look like one trade wearing several jackets.

That is hidden concentration.

Hidden concentration is more dangerous than visible concentration because it comes with false comfort. The portfolio appears diversified by line item, geography, and narrative. But the underlying risk can still be the same.

So the next phase of portfolio construction is not:

What else looks attractive?

It is:

What makes money if the core portfolio is wrong?

This is the point at which portfolio construction becomes more than trade selection.

It becomes risk architecture.

Marginal Contribution: What a Trade Does to the Portfolio

The most important table in a portfolio review is often not

expected return.

It is marginal contribution to risk.

Standalone risk asks:

How much can this trade move by itself?

Marginal risk asks:

What does this trade do to the portfolio?

Those are different questions, and they deserve different answers.

In the illustrative analytics, some trades have meaningful standalone volatility but add very little aggregate risk. The full portfolio table shows the difference between standalone volatility, marginal contribution, and share of portfolio volatility.

	Trade Description
Conviction Trade #1	Long UK Gilts vs US Treasuries Long 20y UK Gilts on the 10s20s30s fl Flatten UK 10s30s cash curve
Conviction Trade #2	Long 30y EU on ASW 6s
Adjacent Theme	France 5s10s Steepener RV Long France vs Germany 5f5Y
Counter-balancing trades	Pay 2y Japan TONAR swaps Short 10y Italy vs Spain Short the Bund vs Bobl as an ASW 6s b
	Portfolio Agregate

Notes: diversification across strategies has halved the risk in the portfolio

Notes: even with diversification our two highest conviction trades contri

Notes: quarterly portfolio volatility is 255bps (2.55%) with a sharpe of two

Figure 2. Portfolio volatility table: standalone volatility, marginal risk contribution, and share of portfolio volatility by trade expression.

The table also shows that diversification does not mean equalisation. The two highest-conviction themes still account for just over 82% of portfolio volatility, even after diversification. The long 30-year EU ASW expression is the largest single contributor at 105bps per quarter, or 40.3% of portfolio volatility. One French

steepener expression has a negative marginal contribution of -8bps, or -3.1%, because it offsets other risks in the structure.

That is valuable.

But it is not free.

Negative marginal risk usually means a trade is offsetting something else in the portfolio. If that relationship changes - for example, in a systemic stress where correlations shift - the diversifier can quickly become a source of risk.

So low or negative marginal-risk trades should be treated with respect, not complacency.

They are powerful because they create room in the portfolio. But they still need their own thesis, their own liquidity assessment, and their own failure condition.

The most valuable trade is not always the one with the highest standalone Sharpe. Sometimes it is the one that allows the rest of the portfolio to exist.

Regime Awareness

The same position is not the same risk in every market regime.

A portfolio that looks balanced in a quiet volatility regime can become too large when volatility rises, liquidity deteriorates, or correlations become less stable. That is why portfolio volatility should be monitored against both shorter-term and longer-term history.

In this case study, the aggregate portfolio volatility

estimate is approximately 255bps per quarter, but that number is only useful when placed in regime context. If realised volatility rises materially, the same nominal position size represents a larger claim on the risk budget. If volatility falls, the portfolio may have more room, but the quality of diversification still has to be tested.

Figure 3. Regime awareness: short- and long-window estimates of aggregate portfolio volatility.

Sizing is therefore not a one-off decision. It is a risk dial. When the regime changes, the portfolio has to change with it.

The Anti-Portfolio

Every portfolio design should define its inverse.

Call it the anti-portfolio: the part of the structure designed to protect against the state of the world in which the portfolio's assumptions are most likely to fail.

This is not just a scenario checklist. It is portfolio

insurance.

The anti-portfolio matters because investors are not always given time to react. In a clean backtest, the portfolio can be reviewed calmly after each move. In a real stress, the market can gap, liquidity can disappear, correlations can shift, and the facts can change before there is time to reduce risk deliberately.

That is where the anti-portfolio earns its place.

It is designed to help in the tails: not because the investor wants the core thesis to be wrong, but because the cost of being wrong can be nonlinear when the portfolio has no built-in offset.

For this type of rates portfolio, the obvious anti-portfolio is global inflation re-acceleration.

Imagine energy prices rising, wage data staying sticky, central banks pushing back against cuts, fiscal risk remaining high, and long-end supply continuing to pressure term premia.

In that world, long-duration exposures struggle. Fiscal curves steepen. Spread products may not provide immediate offset. Liquidity can deteriorate before valuation has time to matter.

That scenario does not invalidate the portfolio.

But it tells the risk manager what protection needs to exist before the shock arrives.

Anti-Portfolio Shock

Why It Matters

What the Insurance Is For

The purpose is not prediction.

The purpose is pre-emption.

The anti-portfolio is what protects the portfolio during the interval between recognising that the thesis is wrong and being able to act on that recognition.

A portfolio without an anti-portfolio is just a story waiting to be contradicted.

See Appendix F for additional notes on review levels, liquidity, and failure conditions.

The Risk Dial

There is a misconception in macro investing that risk management simply means placing a hard stop on every trade and walking away.

That is not always how discretionary macro works.

A hard stop can make the portfolio a forced seller at the worst possible moment. It can turn volatility into liquidation. It can force an exit not because the thesis has changed, but because the price has moved.

Instead, each trade should have a review level.

A review level is not an automatic liquidation point. It is a forced decision point. It exists to reduce the emotional temperature and make the investor answer a simple question:

Has the fact set changed?

When a trade hits a review level, there are three possible responses.

Situation	Response
Price worse, facts worse	Reduce risk
Price worse, facts unchanged	Reassess; potentially add if risk budget and liquidity allow
Facts better, price unchanged	Consider increasing exposure

The purpose of the process is not to avoid adverse price movement. Adverse price movement is part of investing.

The purpose is to avoid emotional decision-making when adverse price movement arrives.

Panic is usually what happens when there are no pre-agreed decision rules.

Where This Breaks

No construction process is magic.

The weak point is always correlation.

In a true liquidation, the market does not care that two trades have different rationales. Investors sell what they can. Balance sheet becomes scarce. Liquidity premia dominate. Diversification that looked robust in normal conditions can compress brutally.

That is why portfolio analytics should be treated as instrumentation, not truth.

The numbers show what the portfolio has behaved like. They do not guarantee how the portfolio will behave when everyone is trying to exit the same theatre through the same door.

When correlations move toward one, reduce gross.

When volatility regime changes, resize.

When liquidity deteriorates, respect exit capacity.

When the reason for a trade is invalidated, exit.

When a hedge stops hedging, do not admire it for its original intention.

The discipline is not only in building the portfolio.

It is in admitting when the portfolio that was built is no longer the portfolio that is owned.

Final Thought

The individual trades matter. They always will.

But they are not the product.

The product is the portfolio: a structure built deliberately, layer by layer, where each position earns its place not only because it has standalone merit, but because of how it interacts with everything else.

That is how 548bps of summed standalone quarterly volatility can behave like 255bps of aggregate marginal portfolio risk. That is how meaningful gross exposure can live inside a tighter risk budget.

That is how a macro rates portfolio can pursue meaningful P&L without simply betting the house on one view.

The framework is not:

I have eliminated risk.

It is:

I know what risk is owned, why it is owned, how it can fail, and what would justify changing exposure before emotion takes over.

Each trade earns its place on standalone merit.

The portfolio earns its Sharpe from how those trades interact.

It is not magic.

It is strategy.

Appendix: Trade Expression Notes

The main article describes the portfolio at the level of role, interaction, and risk structure. This appendix preserves the trade-expression detail for readers who want to inspect the components more closely.

Appendix A - Long-End Gilt Risk Premium

The first core idea was a risk premium sitting in the long end of the gilt market.

Long gilts appeared cheap on asset swap, cheap on the curve, and cheap cross-market. That matters because the best trades rarely screen well on only one metric. They tend to look out of place from several angles at once.

The curve appeared too steep for the level of rates and relative to cross-market relationships. The supply picture was becoming more favourable just as growth softened, fiscal tightening started to matter, and inflation pressure eased. Together, those conditions argued for a lower term-premium environment ahead.

The analytical framework was designed to identify those moments: long-term macro relationships, statistical screens, scenario analysis, and relative-value comparisons pointing in the same direction.

The objective is not to produce a magic signal. It is to force discipline:

- Where is the market stretched?
- What is driving the stretch?
- What has to happen for the stretch to unwind?
- What would prove the thesis wrong?

In this case-study period, long-end gilts were screening attractively across several parts of the framework. The more interesting point was that the drivers of cheapness were exposed to a potential delta flip. The same forces that had pushed risk premium higher could plausibly start working in reverse.

The Budget was the obvious risk event. It had caused real pain in gilts previously, so investors carried scar tissue into the next fiscal event. But the setup had changed. Positioning was already pessimistic. Fiscal space appeared more constrained. Supply anxiety was widely understood. And the narrative tailwind behind long-end cheapening was losing force.

Valuation was stretched.

Positioning was cleaner.

Supply anxiety was visible.

The narrative was tired.

That is not the end of the process.

It is the beginning.

Appendix B - EU 30-Year Relative Value

The second core idea was in long-dated EU bonds.

The EU long end had high credit quality, but still traded with features more typical of agency or quasi-sovereign paper. It was trading at a steep premium to swaps and materially wide to core European sovereign comparables.

On the surface, there were understandable reasons for that.

The EU was still treated by many investors as closer to an agency than a sovereign. Supply was not as front-loaded through the year, which meant issuance could arrive in seasonally difficult windows. The asset also behaved like a high-beta spread product, so when investors reduced speculative risk into year-end, EU paper tended to suffer.

That was the market's explanation.

The question was whether the explanation was already in the price.

Screening, scenario, and valuation tools pointed to a divergence between momentum and fundamental value. Near-term supply was increasingly priced. The premium was large. The rationale for the discount was becoming stale.

The logic chain was straightforward.

If the EU was cheap because it was not treated as a sovereign, and if that treatment was linked to the temporary nature of the funding programme, then the future issuance path mattered. Either large net new supply eventually faded, in which case the EU bond market could gradually develop scarcity value; or a new programme emerged, in which case the EU became a more permanent funding vehicle with a stronger case for broader index treatment and sovereign-like investor demand.

In either scenario, the valuation discount had a plausible path to compression.

This was not the same type of trade as the gilt position.

The gilt trade was more tactical: valuation stretch, positioning, fiscal-event risk, supply timing, and narrative exhaustion.

The EU trade was slower: classification, issuance regime, investor base, structural spread compression.

One was a sprint to the next catalyst.

The other was a marathon toward a changed equilibrium.

That difference in horizon is not incidental. It is one of the reasons both can belong in the same portfolio.

Appendix C - German Asset-Swap Curve

One complementary trade came from the German asset-swap curve.

European front-end repo had been stabilising around relatively normal levels after a prior period of sharp year-end cheapening. The memory of that cheapening was still fresh. That is often a useful backdrop: when investors remember the pain, the premium may still be available.

At the same time, German duration supply was rising given the shift in fiscal stance. Fiscal spending was expected to increase, Bund supply was rising into weak fundamentals, and the market was being asked to absorb more term risk.

Historically, paying pressure in 10-year Europe has affected this part of the swap curve differently from other jurisdictions. That made the German 5s10s asset-swap area look rich in some relative comparisons.

The German asset-swap curve therefore had its own standalone logic.

But its real value was at the portfolio level.

It had the potential to work in the world that would hurt long-end gilt longs: a world where investors priced larger deficits, more supply, and higher term premia.

That is exactly what the portfolio needed.

This trade was not just another return stream.

It was a shock absorber.

Appendix D - French Steepeners

France added another type of risk: political uncertainty that refused to leave the room.

Persistent political stress had kept parts of the French curve and cross-market premia distorted, creating recurring relative-value opportunities. A French steepening expression was attractive because it had positive carry and could perform in a heightened political-risk environment.

This mattered because France, Japan, and the UK had all been frequent targets in a regime where investors were sensitive to fiscal credibility, supply, and political stability.

A French steepener therefore offered a natural offset to flattening trades and fiscal-risk exposure elsewhere in the portfolio.

Outright valuations were not always compelling, so the expression mattered. A forward France-versus-Germany steepening structure could isolate French risk more cleanly and reduce unwanted global duration beta. That flexibility allowed the portfolio to choose between outright and relative expressions depending on the desired risk profile.

This is one of the quiet rules of good portfolio construction:

Do not let a hedge become another version of the trade it is supposed to hedge.

Every layer should have a job.

[Return to main article.](#)

Appendix E - Credit Wideners

The final layer addressed a different regime.

When rates volatility falls, credit risk premium often compresses. The market relaxes. The hierarchy of credit quality remains, but the distance between stronger and weaker credits narrows. Investors convince themselves that the carry is enough compensation because nothing has happened recently.

That is often when the option on stress becomes cheaper.

With parts of the European government-bond credit curve trading very flat, it was possible to move up in quality at relatively low cost. That created a way to own protection against spread stress while imposing only a modest carry drag.

One expression was to be short weaker sovereign credit risk against a blend of higher-quality credits. In benign environments, the spread could trade closely enough that the carry drag remained manageable. But if liquidity deteriorated, the weaker credit would be expected to underperform disproportionately.

This trade was not an attempt to forecast a crisis.

It was a way of buying a cheap claim on the market remembering that credit risk exists.

That is very different.

[Return to main article.](#)

Appendix F - Review Levels, Liquidity, and Failure Conditions

The risk dial is constrained by liquidity. A structural 30-year relative-value trade cannot be risk-managed like a liquid futures hedge. A position can only be sized as aggressively as its exit capacity allows.

That is particularly important for carry and credit risk. Investors often misallocate there because they look at ex-ante risk-adjusted carry. They want to own risk when it feels safe. But perceived safety and realised safety are often inversely related.

When everyone is relaxed, risk is often building.

When everyone is worried, risk may already be priced.

Risk should be released counter-cyclically.

A review level is not a mechanical stop. It is a forced decision point.

When a trade hits a review level, the investor should ask:

- Has the thesis changed?
- Has the liquidity profile changed?
- Has the correlation structure changed?
- Has the role of the trade inside the portfolio changed?
- Has the trade become too large relative to its exit capacity?

The purpose is to avoid being forced into decisions by emotion, liquidity, or mark-to-market pressure.

The trade may be reduced.

It may be left alone.

It may even be increased.

But the decision should be deliberate.
